### (54) Slide driving apparatus of press machine.

(57) A Slide driving apparatus of press machine, wherein a main gear 3 as a rotational drive member and a lever member 10 as a driven member are opposed to one another in a eccentric state which an axes O<sub>1</sub> and O<sub>2</sub> are separated, the main gear 3 and the lever member 10 being connected to one another by a connecting member 13 consisting of a pin member 11 and a bush member 12. A drive rotation locus A which can be traced, round the axis O<sub>1</sub>, by a movement of a connecting center O<sub>5</sub> where the main gear 3 and the connecting member 13 are connected, and a driven rotation locus B which can be traced, round the axis O<sub>2</sub>, by a movement of a connecting center O<sub>4</sub> where the lever member 10 and the connecting member 13 are connected, intersect one another at points of C and D. A slide of the press machine is connected, by the connecting rod, to an eccentric portion 8A of the crankshaft 8 where

the lever member 10 is fixed.

The present invention relates to a driving apparatus for a slide in a press machine which goes up and down reciprocally, which being useful for a quick-return motion of the slide.

There is a conventional press machine which attains a precise press and an efficient production, because of a slide which decreases its down-speed in a processing range and increases its up-speed beyond certain level from a bottom dead center which means the lowest position of the slide through its reciprocal movement. Such systems as using a slip element (described in Japanese Utility Model Application Laid-open No. 57-76997) and an eccentric link (described in Japanese Patent Application Laid-open No. 62-275599) are well-known in this art. The slip-element type system is schematically shown in Figures 4 and 5. The eccentric-link type system is also shown in Figures 6 and 7.

The following explanation will be accompanied by Figures 4 and 5. Denoted by 51 is a pinion which is driven by a motor as a drive source and fits into a main gear 52. A lever 53 opposite the main gear 52 is fixed to one end of a crankshaft 54 of which an eccentric portion 54A is connected with a slide 56 by means of a connecting rod 55 that comes in therebetween. The lever 53 has a long guide groove 53A on its surface so that a slip element 58, on a forward end of a rotation axle 57 provided on the main gear 52, can move along the guide groove 53A. A rotation axis  $O_6$  for the main gear 52 differs from a rotation axis  $O_7$  for the lever 53 (an axis of the crankshaft 54 as well) by  $\theta_3$ .

When the main gear 52 is rotated by the pinion 51, the slip element 58 moves the lever 53 and the crankshaft 54 and then carry the slide 56 either upwardly or downwardly. As shown in Figure 5, when the lever 53 is turned round the axis  $O_7$  at an angle of 180 degrees from a position drawn by full line and shifted to another position 53' shown by dotted line, the main gear 52 will rotate round the axis  $O_6$  at an angle of  $\theta_3$ . Following this shift, if the lever 53 is further rotated at an angle of 180 degrees so as to return to the position drawn by full line, the main gear 52 will rotate at an angle of  $\theta_4$ . Since the axis  $O_7$  differs from the axis  $O_6$ , the angle  $\theta_3$  is narrower than 180 degrees and the angle  $\theta_4$  is wider than 180 degrees. Accordingly, if the main gear 52 constantly rotates and the slide 56 stays at its bottom dead center when the lever 53 is at the position drawn by full line, it will not take more time for the slide 56 to move from its bottom dead center to top dead center (that is, to move upwardly) than to move from its top dead center to bottom dead center (that is, to move downwardly). In consequence, the upward motion of the slide become quick.

The following explanation for the eccentric-link type system will be accompanied with Figures 6

and 7. A pinion 61 driven by a motor, as a drive source, fits into a main gear 62 which turns by means of a set of bearings 63. At an inside of the bearings 63, a crankshaft 64 is held so as to rotate. The crankshaft 64 is connected with a slide 66 by means of a connecting rod 65 that comes in therebetween. The joint between the crankshaft 64 and the connecting rod 65 is done at an eccentric portion 64A. On a surface of the crankshaft 64, a yoked type lever portion 64B is provided between the bearings 63. The lever portion 64B is connected to a yoked type main portion 62A of the main gear 62 by means of a link 67 which joins with these two portions by pins 68 and 69. A rotation axis  $O_8$  for the main gear 62 differs from a rotation axis  $O_9$  for the lever portion 64B (an axis of the crankshaft 64 as well) by  $\theta_4$ .

When the pinion 61 drives the main gear 62, this motion will be transmitted to the crankshaft 64 via the link 67 and the lever portion 64B so as to move the slide 66 upwardly or downwardly. In Figure 7, when the pin 68 of the crankshaft 64 is rotated round the axis  $O_9$  at an angle of 180 degrees and consequently shift to a position 68' drawn by dotted line, that is, when the crankshaft 64 is rotated at an angle of 180 degrees, the pin 69 of the main gear 62 will shift from a position drawn by a full line to another position 69' drawn by dotted line on the axis  $O_8$ . In this situation, a rotation angle of the main gear 62 becomes  $\theta_5$ . Following this change in position, when the crankshaft 64 further turn at an angle of 180 degrees so that both the pins 68' and 69' return to the positions drawn by a full line, respectively, a rotation angle of the main gear 62 becomes  $\theta_6$ . Since the axis  $O_9$  differs from the axis  $O_8$ , the angle  $\theta_5$  is narrower than 180 degrees and the angle  $\theta_6$  is wider than 180 degrees. Accordingly, if the main gear 62 constantly rotates and the slide 66 stays at its bottom dead center when the pins 68, 69 are at the respective positions drawn by full line, it will not take more time for the slide 66 to move from its bottom dead center to top dead center (that is, to move upwardly) than to move from its top dead center to bottom dead center (that is, to move downwardly). In consequence, the upward motion of the slide become quick.

Figure 8 shows a slide motion denoted by "P" in the slip-element type system drawn in Figures 4 and 5 and a slide motion denoted by "Q" in the eccentric-link type system drawn in Figures 6 and 7. In Figure 8, each phase angle of the crankshafts in both systems is adjusted so as to both curve lines of the motions P and Q overlap one another from the top dead center to the bottom dead center of the slides. In the eccentric-link type system, when the rotation of main gear 62 is transmitted to the crankshaft 64 via the link 67, the rotation speed

of the crankshaft 64 is varied from fast to slow, because of a constant angle swing round the pin 69. Accordingly, if the link 67 is disposed such that the slow down of the rotation speed of the crankshaft 64 comes out when the slide is almost near to the bottom bead center, the tilted angle (which shows a speed of the slide) of the motion  $Q_{11}$  is less than that of the motion  $Q_{10}$ . Hence, the curve line of the motion Q becomes like a bottom shape of a wok (a deep round pan).

Because of such curved slide motion Q, the slide speed in processing (pressing) becomes slow, so that a drawing press will carry out reliably and product goods.

However, in the mentioned slide driving apparatus employing the eccentric-link type system, the following problems were brought about.

In Figure 7, a circle denoted by E, round an axis  $O_8$ , is a drive rotation locus of center portion where the main gear 62 and the link 67 are connected one another by the pin member 69 when the main gear 62 rotates once, a circle denoted by F, round an axis  $O_9$ , is a driven rotation locus of center portion where the lever portion 64B of the crankshaft 64 and the link 67 are connected one another by the pin member 68. Figure 11 shows an swing angle  $\beta$  of the link 67, when one rotation of the main gear 62 is transmitted to the crankshaft 64 as described in Figures 6 and 7. A length L caused by the swing angle  $\beta$  can vary the rotation speed of the crankshaft 64 from fast to slow so as to trace the slide motion Q. While the link 67 moves such that the both end portions thereof trace the locus E and F respectively and swings at an angular  $\beta$  corresponding to one rotation of the main gear 62, rotation speed of the crankshaft 64 is fluctuated along a curve line G shown in Figure 9, so that speed of the slide 66 is effected by the fluctuated rotation of the crankshaft 64, which is described by a curve H in Figure 10.

In Figure 9, maximum rotation speed of the crankshaft 64 is  $V_1$ , and minimum one is  $V_2$ . High precise pressing by the slide motion Q, as shown in Figure 8, needs the tilted angle  $\theta_{11}$  less than certain value. To obtain such tilted angle  $\theta_{11}$ , ratio  $V_1/V_2$  should be high because  $V_1$  means high rotation speed of the crankshaft 64 owing to swing of the link 67 and  $V_2$  means low rotation speed. But, according to the conventional eccentric-link type system, length difference between a radius  $R_3$  of the drive rotation locus E and a radius  $R_4$  of the driven rotational locus F is made large to keep the locus F inside of the locus E, so that the link 67 do not interfere with any other member while swinging. From a different view, the link 67 is to have a certain length and be tilted toward the rotation direction so that the rotation of the main gear 62 is transmitted to that of the crankshaft 64. Accord-

ingly, in order to increase  $V_1/V_2$  until the certain value and obtain the length L by the angle  $\beta$ , the eccentric distance  $e_4$ , shown in Figures 6 and 7, should be long.

For these reasons, a diameter, of a rotation center portion where an eccentric portion of the apparatus is provided, becomes long, whereby a scale of the apparatus is likely to become big.

An object of the present invention is to provide a slide driving apparatus which attains a miniaturization of the apparatus by miniaturizing a diameter of the rotation center portion.

An apparatus, in the present invention, for driving a slide by means of a crankshaft and a connecting rod in a press machine has: a rotational drive member capable of being rotated by a drive source and a corresponding driven member fixed to the crankshaft, in a state that both axes of the rotational drive member and the driven member are separated and opposing to one another; and a connecting member having two connecting centers, the first of which separates from the axis of the rotational drive member and is to be connected with the rotational drive member, the second of which separates from the axis of the driven rotation member and is to be connected with the driven rotation member, so that a drive rotation locus of the first connecting center round the axis of the rotational drive member and a driven rotation locus of the second connecting center round the axis of the driven rotation member intersect one another, an eccentric portion of the crankshaft being connected to the slide through the connecting rod.

Otherwise, an apparatus, in the present invention, for driving a slide by means of a crankshaft and a connecting rod in a press machine has: a rotational drive member capable of being rotated by a drive source and a corresponding driven member fixed to the crankshaft, in a state that both axes of the rotational drive member and the driven member are separated and opposing to one another; a pin member of which one end portion is standing out from one surface of either the rotational drive member or the driven member along each axis; and a bush member capable of rotating in a state to be coupled into either the member which do not have the pin member, the pin member being coupled into the bush member at a distant point from an axis thereof and an eccentric portion of the crankshaft being connected with the slide through the connecting rod.

The preferable rotational drive member is the main gear driven by the pinion, but it is also available to be a gear train or a disc-like member or a lever member which is driven by the drive shaft. The corresponding driven member is preferably to be the lever member, but a disc-like member or a lever member formed with the crankshaft

is also available.

When the rotational drive member is rotated by the drive source, this motion will be transmitted to the driven member through the connecting member consisting of the pin member and the bush member. Subsequently, the crankshaft is rotated to make the slide go up and down reciprocally. Since the axis of the rotational drive member is separated from that of the driven member, return movement of the slide becomes quick.

When the rotation of the rotational drive member is transmitted to the driven member, rotation speed of the crankshaft become irregular due to different axes. Besides, the drive rotation locus and the driven rotation locus crosses one another, so that gap between maximum rotation speed and minimum rotation speed becomes big. Therefore, even though the eccentric distance between the rotational drive member and the driven member is small, the ratio; maximum rotation speed against minimum rotation speed of the crankshaft, becomes high. In different view, the transmission from the rotational drive member to the driven member is done through the bush member. A distance, from an axis of the bush member to a center of the pin member which is coupled into the bush member, can correspond to a dimension of a link which is employed in a conventional eccentric-link type system. Such arrangement can attain a wide rotation angle of the bush member while the rotational drive member and the driven member rotate once. Hence, even though the dimension of the link in the present invention is short, a necessary length can be obtained so as to cause fluctuation of rotation speed for the crankshaft like in the conventional eccentric-link type system. Accordingly, the distance between axes of the rotational drive member and the driven member can be minimized, so that the diameter at the rotating portion where the eccentric portion of the apparatus is provided can be made small in size.

In the accompanying drawings:

Figure 1 is a front view showing the apparatus in the preferable embodiment according to the present invention. Figure 2 is a schematic side view of the apparatus shown in Figure 1. Figure 3 is a schematic diagram for explanation of operation in Figures 1 and 2. Figure 4 is a schematic representation showing the conventional apparatus employing a slip element type system. Figure 5 is a schematic diagram for explanation of operation in Figure 4. Figure 6 is a schematic representation showing the conventional apparatus employing an eccentric-link type system. Figure 7 is a schematic diagram for explanation of operation in Figure 6. Figure 8 is a graphical representation of the slide motion which can return quickly. Figure 9 is a graphical

representation of rotation speed of the crankshaft. Figure 10 is a graphical representation of speed of the slide. Figure 11 is an explanation view for swing angle of the link in order to obtain certain length.

A preferable embodiment of the present invention will hereunder be described accompanying with attached drawings.

Figure 1 is a front sectional view of an apparatus in the embodiment. Figure 2 is a schematic side view of the apparatus. In Figure 1, a drive shaft 1 which is driven by a motor as a drive source has, on one end, a pinion 2 fitting into a main gear 3. The main gear 3 so relates to a large diameter bearing member 6, which is held by a boss member 5 of a frame 4, that the gear 3 can be rotated by the pinion 2 round an axis O<sub>1</sub>. The main gear 3 is used in this embodiment as a rotational drive member. The bearing member 6 has a hole 6A for holding one potion of a crankshaft 8. The other portion of the crankshaft 8 is also held by a boss member 7 at its inner hole 7A. An axis O<sub>2</sub> is separated from the axis O<sub>1</sub> by a distance of e<sub>1</sub>. The crankshaft 8 has a round shaped eccentric portion 8A as shown in Figure 2. An axis of the eccentric portion 8A is denoted by O<sub>3</sub> in the drawing and separated from the axis O<sub>2</sub> by a distance of e<sub>2</sub>. The eccentric portion 8A is to be a portion to be connected with an upper portion of a connecting rod 9. While, a lower portion of the connecting rod 9 is connected to a not-shown slide, so that the slide will go up and down reciprocally two times longer than usual.

As shown in Figure 1, one end portion of the crankshaft 8 is extended from the bearing member 6 and has a lever member 10 extending along a radial direction of the crankshaft 8. The lever 10, which is rotated so as to correspond with the rotation of the main gear 3, is employed as a driven member in this embodiment. The axis of the lever 10 is the same as the axis O<sub>2</sub> of the crankshaft 8. Consequently, the lever 10 is eccentric from the main gear 3 by e<sub>1</sub> and opposes to the main gear 3 on the same axis.

The main gear 3 has a hole in which a base portion 11A of a pin member 11 is inserted and held such that a potion of the pin member 11 stands out straight from one surface of the main gear 3. The lever member 10 has a hole 10A at nearly its forwarded end portion and distant from the axis O<sub>2</sub>. The hole 10A is provided for holding a bush member 12 to rotate round the axis O<sub>4</sub> as shown in Figure 2. As can be seen from Figure 1, a forwarded end portion 11B of the pin member 11 is coupled into the bush member 12 and can rotate round an axis O<sub>5</sub> separating from the axis O<sub>4</sub>.

Incidentally, a combination of the pin member 11 and the bush member 12 is to be called a

connecting member 13 for connecting the main gear 3 with the lever member 10. The axis  $O_5$  is of a center for connecting the main gear 3 with one end portion of the connecting member 13 and the axis  $O_4$  is of a center for connecting the lever member 10 with the other end portion of the connecting member 13. When the main gear 3 is rotated once, the axis  $O_5$  traces over the drive rotation locus A described in Figures 2 and 3 round  $O_1$  and the axis  $O_4$  does the driven rotation locus B round  $O_2$ . In this embodiment, the radius  $R_1$  of the locus A is almost the same as the radius  $R_2$  of the locus B, so that the locus A and B intersect one another at points C and D.

An operation of the mentioned embodiment will hereunder be explained.

When the main gear 3 is rotated by the pinion 2 round the axis  $O_1$ , the rotation of the main gear 3 will be transmitted to the lever member 10 through the pin member 11 and the bush member 12. Through this state, both of the lever member 10 and the crankshaft 8 rotate round  $O_2$ . So that the slide will go up and down reciprocally by means of the connecting rod 9. The rotational transmission from the main gear 3 as the rotational drive member to the lever member 10 as the driven member is done with the bush member 12 which is rotated at certain angle round  $O_4$  and with the pin member 11 which is rotated as well round  $O_4$ . Hence, the axis  $O_5$  moves on the drive rotation locus A and the axis  $O_4$  moves on the driven rotation locus B. When the locus A of the axis  $O_5$  round the axis  $O_1$  comes out, that is, the rotation of the main gear 3, the lever 10 or the crankshaft 8 is finished once corresponding to the rotation of the bush member 12 round the axis  $O_4$ , so that the pin member 11, of which the forwarded end portion 11B is coupled into the bush member 12, will be shifted at an angle of certain degrees as shown in Figure 3. Though the pin member 11 rotates round  $O_4$ , the pin member 11 does not interfere any other member owing to the connecting member 13.

In Figure 3, when the bush member 12 moves to a position denoted by 12' after rotating at an angle of 180 degrees round the axis  $O_2$ , the pin member 11 is correspondingly changed to a position denoted by 11'. Through this motion, a rotation angle of the pin member 11 round the axis  $O_1$  is equal to a rotation angle  $\theta_1$  of the main gear 3. While, if the bush member 12 is returned from the position 12' to the prior position, the pin member 11 will be also replaced to its prior position. In this process, a rotation angle of the pin member 11 is equal to the rotation angle  $\theta_2$  of the main gear 3. Since the axis  $O_1$  is separated from the axis  $O_2$  by a distance  $e_1$ , the angle  $\theta_1$  is more narrow than 180 degrees and the angle  $\theta_2$  is wider than 180 degrees. Accordingly, if the positional relationship

between the pin member 11 and the eccentric portion 8A of the crankshaft 8 is defined as shown in Figure 2 and if the position of the slide shown in Figure 2 is defined to be its bottom dead center, the necessary time for the slide from its bottom dead center to top dead center is shorter than the opposite motion. In consequence, the upward motion of the slide become quick.

In Figures 2 and 3, when the axes  $O_4$  and  $O_5$  go through an area where the driven rotation locus B is inside of the drive rotation locus A, that is, through an upper side of the intersecting points C, D of the loci A, B, the rotation speed of the main gear 3 is decreased and transmitted to the crankshaft 8. On the contrary, when the axes  $O_4$  and  $O_5$  go through an area where the driven rotation locus B is outside of the drive rotation locus A, that is, through an lower side of the intersecting points C, D of the loci A, B, the rotation speed of the main gear 3 is increased and transmitted to the crankshaft 8.

Since the loci A and B intersect at the points C and D, even though the eccentric distance  $e_1$  from the axis  $O_1$  to the axis  $O_2$  is small, rotation speed difference of the crankshaft 8 between its maximum and minimum becomes enough. Therefore, the ratio;  $V_1/V_2$  in Figure 9 can be increased upon the necessity. This means to attain enough tilted angle  $\theta_{11}$  in Figure 8 so as to secure the slide motion Q of accurate pressing. Such small eccentric distance  $e_1$  brings small in size to the apparatus, because the rotational center portion where the eccentric portion of the apparatus is provided, especially a diameter at circumference of the bearing member 6 and the crankshaft 8, becomes small in size.

As can be known from Figure 2, a substantial length of the lever member 10 is shown by " $R_2$ " which is a distance between two axes  $O_2$  and  $O_4$ . A mechanism employed in this embodiment seems to be comprised with the lever member 10 having a length  $R_2$  and a link having a length  $l$  from the axis  $O_4$  to the axis  $O_5$  of which one end portion is connected with the main gear 3. In mechanical view, such structure is likely to be the mentioned conventional apparatus having the lever portion 64B and the link 67, as shown in Figure 6.

The apparatus, in this embodiment, employs the main gear 3 having the pin member 11 which is coupled into the bush member 12 rotating in the inside of the hole 10A of the lever member 10, so that the rotation of the main gear 3 makes the bush member 12 rotate, through the pin member 11, round the axis  $O_4$  and is transmitted to the lever member 10. This causes a wide rotation angle of the bush member 12 round the axis  $O_4$  when the main gear 3, the lever member 10 and the crankshaft 8 are rotated once all together.

As described above, the slide motion Q, drawn in Figure 8 for a high precise pressing of material, can be obtained by the length L drawn in Figure 11 which causes a deviation of the rotation speed of the crankshaft. While, in this invention, since the rotation angle of the bush member 12 round the axis O<sub>4</sub> can be made widely, a swing angle  $\alpha$  of the link 14, which has a length l equal to the distance between two axes O<sub>4</sub> and O<sub>5</sub> as can be seen from Figure 11, becomes wide. Therefore, according to the present invention, to obtain the length L of the link 14 having the distance l is easier than by the link 67 shown in Figures 6 and 11.

Consequently, the necessary length L can be kept, even though the distance  $e_1$ , which is a distance between the axis O<sub>1</sub> for the main gear 3 and the axis O<sub>2</sub> for the lever member 10 and the crankshaft 8, is made short. This means that the slide motion Q in Figure 8 can be achieved by the short distance  $e_1$ , so that a rotatable center portion influenced by the distance  $e_1$ , that is, such portions as the crankshaft 8, the bearing member 6, or the like, will become small in size. This is therefore desirable for the apparatus to minimize its size.

In the disclosed embodiment, the pin member 11 was provided at the side of the main gear 3 and the bush member 12 was done at the side of the lever member 10. However, this arrangement can be changed round.

The connecting member 13 to join the rotational drive member with the driven member consists of the pin member 11 and the bush member 12 in the mentioned embodiment. However, the connecting member 13 may be a single link having a rod shape.

The employed rotational drive member is the main gear 3 driven by the pinion 2 in this embodiment, but it is also available to be a gear train or a disc-like member or a lever member which is driven by the drive shaft 1. The corresponding driven member is also not limited to be the lever member 10, but a disc-like member or a lever member formed with the crankshaft 8.

According to the present invention, the rotational center portion where the eccentric portion in the apparatus is provided can be made small in size. Therefore, totally, the apparatus can be made small in size, some members employed in the apparatus can be processed easily and then the working efficiency and the necessary cost for production of the apparatus should be improved.

## Claims

- An apparatus for driving a slide by means of a crankshaft and a connecting rod in a press machine comprising:

- 5      a rotational drive member capable of being rotated by a drive source and a corresponding driven member fixed to the crankshaft, in a state that both axes of the rotational drive member and the driven member are separated and opposing to one another; and
- 10     a connecting member having two connecting centers, the first of which separates from the axis of the rotational drive member and is to be connected with the rotational drive member, the second of which separates from the axis of the driven rotation member and is to be connected with the driven rotation member, so that a drive rotation locus of the first connecting center round the axis of the rotational drive member and a driven rotation locus of the second connecting center round the axis of the driven rotation member intersect one another, an eccentric portion of the crankshaft being connected to the slide through the connecting rod.
- 15     2. An apparatus in claim 1, wherein said connecting member consists of a pin member, of which one end portion is standing out from one surface of either said rotational drive member or said driven member, and a bush member capable of rotating in a state to be coupled into said either member which do not have the pin member.
- 20     3. An apparatus in claim 1, wherein said connecting member is to be a single rod shaped link.
- 25     4. An apparatus in claim 1, wherein said rotational drive member is a main gear and said driven member is a lever member.
- 30     5. An apparatus in claim 1, wherein said rotational drive member is a disc-like member driven by the drive source through a gear train.
- 35     6. An apparatus in claim 1, wherein said driven member is a lever member formed with the crankshaft.
- 40     7. An apparatus for driving a slide by means of a crankshaft and a connecting rod in a press machine comprising:
  - 45       a rotational drive member capable of being rotated by a drive source and a corresponding driven member fixed to the crankshaft, in a state that both axes of said rotational drive member and said driven member are separated and opposing to one another;
  - 50       a pin member of which one end portion is standing out from one surface of either said rotational drive member or said driven member
  - 55       ...

along each axis; and

a bush member capable of rotating in a state to be coupled into said either member which do not have said pin member, said pin member being coupled into said bush member at a distant point from an axis thereof and an eccentric portion of the crankshaft being connected with the slide through the connecting rod.

### **(54) Slide driving apparatus of press machine.**

(57) A Slide driving apparatus of press machine, wherein a main gear 3 as a rotational drive member and a lever member 10 as a driven member are opposed to one another in a eccentric state which an axes O<sub>1</sub> and O<sub>2</sub> are separated, the main gear 3 and the lever member 10 being connected to one another by a connecting member 13 consisting of a pin member 11 and a bush member 12. A drive rotation locus A which can be traced, round the axis O<sub>1</sub>, by a movement of a connecting center O<sub>5</sub> where the main

gear 3 and the connecting member 13 are connected, and a driven rotation locus B which can be traced, round the axis O<sub>2</sub>, by a movement of a connecting center O<sub>4</sub> where the lever member 10 and the connecting member 13 are connected, intersect one another at points of C and D. A slide of the press machine is connected, by the connecting rod, to an eccentric portion 8A of the crankshaft 8 where the lever member 10 is fixed.
